Authentication (in crypto)

Crypto is not all about encrypting. One may also want to:

- ▶ Get access to a building/car/spaceship
- ▶ Electronically sign a contract/software/Git repository
- ▶ Detect tampering on a message
- ▶ Detect “identity theft”
- ▶ Etc.

⇒ domain of digital signatures and/or message authentication codes (MACs)

A major rule

In the case of a symmetric channel (e.g. on a network):

- ▶ It may be fine to only authenticate
- ▶ It is *never okay* to only encrypt
 - ▶ Recommended reading: *Attacking the IPsec Standards in Encryption-only Configurations* (Degabriele and Paterson, 2007; <https://eprint.iacr.org/2007/125>)

⇒ "Authenticated encryption" (This is hard to do properly.)

Today: MACs (symmetric authentication)

Message authentication code (MAC)

A MAC is a mapping $\mathcal{M} : \mathcal{K}(\times \mathcal{N}) \times \mathcal{X} \rightarrow \mathcal{T}$ that maps a key, message (and possibly a (random) nonce) to a *tag*.

- ▶ \mathcal{K} is for instance $\{0, 1\}^{128}$ (key space, secret)
- ▶ \mathcal{N} is for instance $\{0, 1\}^{64}$ (“nonce” space, public, either “random” or not)
- ▶ \mathcal{X} is for instance $\bigcup_{\ell < 2^{64}} \{0, 1\}^{\ell}$ (message space)
- ▶ \mathcal{T} is for instance $\{0, 1\}^{256}$ (“tag” space)

⇒ The tag is a “link” between a message and a key

- ▶ Note: MACs are not the *only* way to provide authentication

MACs: what do we want?

Given a MAC $\mathcal{M}(k, \cdot)$ with an unknown key, it should be hard to:

- ▶ Given m , find t s.t. $\mathcal{M}(k, m) = t$ (*Universal forgery*)
- ▶ Find m, t s.t. $\mathcal{M}(k, m) = t$ (*Existential forgery*)
- ▶ (Of course, retrieving k leads to those)

UF: ability to forge a tag for **any** message

EF: ability to forge a tag for **some** messages

UF \Rightarrow EF

MACs: really, what do we want?

More generally, we want $\mathcal{M}(k, \cdot)$ to be like a “variable input-length (pseudo-) random function”

↪ (VIL-) PRF security:

- ▶ An adversary has access to an oracle \mathbb{O}
- ▶ In one world, $\mathbb{O} \stackrel{\$}{\leftarrow} \text{Func}(\mathcal{X}, \mathcal{T})$
- ▶ In another, $k \stackrel{\$}{\leftarrow} \mathcal{K}$, $\mathbb{O} = \mathcal{M}(k, \cdot)$
- ▶ The adversary cannot tell in which world he lives

Where $\text{Func}(\mathcal{X}, \mathcal{T})$ are the functions from the message to the tag space

↪ Define $\mathbf{Adv}^{\text{PRF}}$ in the same way as $\mathbf{Adv}^{\text{PRP}}$

So, how to build a MAC?

- ▶ From scratch
- ▶ Using a block cipher in a “MAC mode”
- ▶ Ditto, with a hash function
- ▶ Using a “polynomial” hash function
- ▶ Etc.

MACs from block ciphers: CBC-MAC example

Observation:

- ▶ The last block of $\text{CBC-ENC}(m)$ “strongly depends” on the entire message
- ▶ \Rightarrow Take $\text{MAC}(m) = \text{LastBlockOf}(\text{CBC-ENC}(m))$
- ▶ Not quite secure as is, but overall a sound idea

Advantage:

- ▶ “Only” need a block cipher

Disadvantage:

- ▶ Not the fastest approach

MACs from hash functions 1

If $\mathcal{H} : \{0, 1\}^* \rightarrow \{0, 1\}^n$ is a hash function, one may define:

- ▶ $\text{PrefixMAC}_{\mathcal{H}} : \{0, 1\}^{\kappa} \times \{0, 1\}^* \rightarrow \{0, 1\}^n$ as
 $\text{PrefixMAC}_{\mathcal{H}}(k, m) = \mathcal{H}(k||m)$
- ▶ $\text{SuffixMAC}_{\mathcal{H}} : \{0, 1\}^{\kappa} \times \{0, 1\}^* \rightarrow \{0, 1\}^n$ as
 $\text{SuffixMAC}_{\mathcal{H}}(k, m) = \mathcal{H}(m||k)$
- ▶ (Note that $\text{PrefixMAC}_{\mathcal{H}} \approx \text{SuffixMAC}_{\mathcal{H}^{\triangleleft}}$, where $\mathcal{H}^{\triangleleft}$ is \mathcal{H} “reversed”)

These constructions are fine *generically* but may be weak for some specific hash functions

Length-extension attack for PrefixMAC

Let \mathcal{H} be a (narrow-pipe) Merkle-Damgård hash function

- ▶ Let $h = \mathcal{H}(m)$ for some m
- ▶ Then $\mathcal{H}(m \parallel \text{pad}(m) \parallel m') = \mathcal{H}_h(m')$

What consequence for the security of $\text{PrefixMAC}_{\mathcal{H}}$?

- ▶ Assume an adversary knows m , $t = \text{PrefixMAC}_{\mathcal{H}}(k, m)$ and $\kappa = |k|$
- ▶ Then $t' = \mathcal{H}'_t(m')$ is a valid tag under k for $m \parallel \text{pad}(m) \parallel m'$
 - ▶ (\mathcal{H}' is \mathcal{H} with an appropriately modified padding)

⇒ Existential forgeries are trivial!

(NB: Problems also exist for $\text{SuffixMAC}_{\mathcal{H}}$ (cf. TD))

(NB: Similar attacks apply to raw CBC-MAC from two slides ago)

MACs from hash functions 2

How to defend against the previous attack?

- ▶ Use a better \mathcal{H} framework, e.g. a *wide-pipe* Merkle-Damgård hash function (e.g. SHA-512/256) or a sponge (e.g. SHA-3)
- ▶ Use a Sandwich MAC construction (e.g. HMAC, SandwichMAC, ...)

HMAC (Bellare et al., 1996):

- ▶ Let \mathcal{H} be a hash function with b -bit blocks, pad a padding to b -bits with zeroes, $\text{opad} = 0x36^{b/8}$, $\text{ipad} = 0x5C^{b/8}$
- ▶ Then

$$\text{HMAC}_{\mathcal{H}}(k, m) = \mathcal{H}(\text{pad}(k) \oplus \text{opad} || \mathcal{H}(\text{pad}(k) \oplus \text{ipad} || m))$$

HMAC facts

- ▶ HMAC is secure up to the birthday bound (of its hash function)
- ▶ It only needs black-box calls to a hash function \Rightarrow simple to implement
- ▶ It is popular (widespread use in e.g. TLS)
- ▶ It is overkill if \mathcal{H} is e.g. wide-pipe
- ▶ Some variants exist, some being more efficient

Block cipher v. Hash-based MACs

Block cipher and Hash-based MACs both use a black box to build a MAC, but

- ▶ Block cipher block sizes are usually “small” (e.g. 64/128 bits)
→ somewhat limited generic security
- ▶ Hash functions are more efficient at processing large amounts of data

⇒ Hash-based MACs tend to be used more than block cipher-based

- ▶ But both loose in speed against polynomial MACs (e.g. VMAC) or dedicated constructions (e.g. PelicanMAC)

Introducing Authenticated-Encryption

The “modern” view:

If you must never encrypt w/o authentication, why separating the two? ⇒ Authenticated-Encryption

- ▶ Maybe more efficient (fewer redundancy)?
- ▶ Maybe more secure (no careless combinations)?
- ▶ Maybe more complex

↪ AEAD (Authenticated-Encryption with Associated Data)

AEAD

An AEAD scheme is a pair of mappings $(\mathcal{E}, \mathcal{D})$ with:

$$\mathcal{E} : \mathcal{K} \times \mathcal{N} \times \mathcal{A} \times \mathcal{X} \rightarrow \mathcal{C}$$

$$\mathcal{D} : \mathcal{K} \times \mathcal{C} \rightarrow \mathcal{X} \cup \{\perp\}$$

- ▶ \mathcal{E} encrypts a message from \mathcal{X} with a key and (possibly) a nonce, and authenticates it together with associated data from \mathcal{A}
- ▶ \mathcal{D} decrypts a ciphertext and returns the message if authentication is successful, or \perp (“bottom”) otherwise
- ▶ Security is typically analysed w.r.t. IND-CPA (for confidentiality) and IND-CTXT (for integrity)

AEAD designs

An AEAD scheme can be built in many ways:

- ▶ By combining a BC mode w/ a MAC (e.g. GCM: CTR mode + a polynomial MAC)
- ▶ As a single BC mode (e.g. OCB)
- ▶ From a sponge construction (e.g. Keyak)
- ▶ From a hash function (e.g. OMD)
- ▶ From a variable input-length wide-block block cipher (e.g. AEZ)
- ▶ Etc.

AEAD: A quick hash function example

Figure: The p-OMD mode (excerpt; source: p-OMD specifications)

pure Offset Merkle-Damgård (Reyhanitabar et al., 2015), based on a keyed hash function (e.g. SHA-256 w/ semi-secret message)

AEAD: A quick VIL-WBC idea

If $\mathcal{E} : \mathcal{K} \times \{0, 1\}^n \rightarrow \{0, 1\}^n$ is a block cipher, one can encrypt *and* authenticate any message m of fixed length $b < n$ by:

- ▶ Computing $c = \mathcal{E}(k, m||0^{n-b})$
- ▶ Decrypting c to m iff. $\mathcal{E}^{-1}(k, c) = m||0^{n-b}$

If \mathcal{E} is “good”, it is “hard” for an adversary to forge \hat{c} s.t. $\mathcal{E}^{-1}(\hat{c})$ ends with $n - b$ zeroes (roughly: success prob. $\approx 2^{b-n}$)

→ Good paradigm, but very limited if \mathcal{E} has typical block size $n \leq 256$

(VIL)-[W]BC

A *Variable input-length wide block cipher* is a family $\mathcal{W} = \{\mathcal{E}^\ell\}$ of mappings $\mathcal{E}^\ell : \mathcal{K} \times \mathcal{X}_\ell \rightarrow \mathcal{X}_\ell$ s.t. for all ℓ , \mathcal{E}^ℓ is a block cipher, where $\ell \in \mathcal{S} \subseteq \mathbb{N}$

- ▶ One can for instance take $\mathcal{X}_\ell = \{0, 1\}^\ell$, $\ell \in [2^7, 2^{64}]$
- ▶ The PRP security of \mathcal{W} is defined as the \min_ℓ PRP security of \mathcal{E}^ℓ
- ▶ †The notion of VIL-WBC is stronger than IND-CPA/CCA symmetric encryption
 - ▶ Exercise: Why isn't encryption with CBC mode a VIL-WBC?

Some various strategies have been proposed to build VIL-WBC

- ▶ Sequential two-pass (e.g. CBC-MAC feeding CTR, Bellare and Rogaway, 1999; CBC forward and backward, Houley; Matyas, 1999)
- ▶ Wide Feistel (e.g. Naor and Reingold, 1997 \leadsto Mr Monster Burrito, Bertoni et al., 2014, and several others)
- ▶ Parallel Feistel (e.g. AEZ, Hoang et al., 2014)

Maybe not the easiest/fastest way, but conceptually beautiful

Conclusion

- ▶ Authentication is essential
- ▶ Most of the time, both encryption and authentication are needed
- ▶ The “modern” way: do both at the same time
- ▶ Still an active research topic (cf. the perpetual CAESAR competition ~
<https://competitions.cr.yp.to/caesar.html>)
